

SUMMARY OF MY FINDINGS

- According to the heatmap the house price was mostly influenced by area then followed by number of bathrooms.
- The Linear Regression model was moderately accurate, its accuracy is about 65.3% ($R^2 = 0.65$). In practical terms, when the model guesses a house's price, it is typically off by an average of about 970,000 units (MAE) from the actual selling price.
- The biggest surprise was that the linear regression model actually outperformed the random forest regression model. Because the dataset is very small and a random-forest category needs to feed from a vast dataset to get better accuracy, linear regression outperformed here.
- As for a recommendation for the real estate business, we should focus more on making the area of houses and no of bathroom big as per recommendation and adjustable for which can generate high revenue for the investors.
